Laboratory No. 3

Name: Briones, Natalie D **Date: March 12, 2026**
Course & Section: BSCS 2B **Sir Bernardino**

PART 1 — Pre-Lab Concept Questions
Answer the following before running the simulation:
1. What is an agent in an Agent-Based Model?

- An agent in an Agent-Based Model is an individual entity in the simulation. It can represent a person, animal, object, or any unit being studied. Each agent has its own behavior and rules to follow. Agents can interact with other agents and their environment. Through these interactions, the model shows how complex systems work.

2. What is the difference between:
- global variables
- species variables?

- Global variables are values that are shared by the whole model. They can be accessed and used by all agents in the simulation. Species variables, on the other hand, belong only to a specific type of agent. They describe the characteristics or properties of that particular group. Because of this, different agent types can have different variables.

3. What does this expression mean?
student mean_of each.attention

- The expression student mean_of each.attention means calculating the average attention level of all student agents. It collects the attention value from each student in the model. After collecting the values, it computes their mean or average. This helps show the overall attention level of the students. It is useful for analyzing the behavior of the group.

4. What happens if attention continuously decreases without a break?

- If attention continuously decreases without a break, the agents' attention level will keep getting lower over time. Eventually, it may reach zero or a very small value. When this happens, the agents may no longer perform their tasks properly. They may stop responding or participating in the simulation. This can affect the overall results of the model.

PART 2 — Run the Base Model
AFTER 100 CYCLES

PART 3 — Data Observation Table Fill in the table after 100 cycles:

Metric	**Value**
Average Attention	**0.834340134**
Average Performance	**0.854772277**
High Attention Count	**25**
Number of Breaks Occurred	**3**

PART 4 — Guided Code Analysis
Activity 1: Break Frequency
Original code: if (cycle mod 30 = 0)
Task: Change break interval to: 15 cycles

Questions:
1. Does attention increase faster?
   - Yes, attention increased faster because breaks occurred more frequently, giving students less time to lose focus between recovery periods.

2. Does performance grow faster?

- Yes, performance grew faster because attention stayed consistently high, allowing the performance increment condition to be satisfied more often throughout the simulation.

3. Is the system more stable?

- Yes, the system is more stable because frequent breaks prevent attention from decaying too low, keeping students at high attention levels throughout the simulation.3

Activity 2: Attention Decay Rate

Original: attention <- max(0.0, attention - 0.02);

Task: Change decay rate to: 0.05

Observe:

1. Does attention collapse?

- Yes, attention dropped much faster. With a decay rate of 0.05, attention runs out quicker between breaks, causing students to lose focus faster compared to the original rate.

2. Does performance still improve? Explain why.

- No, performance doesn't improve that much because it becomes much slower. Since attention drops faster, it spends less time above the 0.6 needed for performance to grow, resulting in lower overall performance compared to the original rate.

Activity 3: Performance Growth Condition

Original: if (attention > 0.6)

Task: Change threshold to: 0.8

Questions:

1. Does performance improve slower?

- Yes, performance improved slower because fewer cycles satisfied the higher threshold of 0.8, reducing how often performance could increment.

2. What does this represent in real classroom settings?

- It represents that students need a higher level of focus and engagement to achieve meaningful learning gains, similar to how complex topics require deeper concentration to understand.

PART 5 — Experiment: Class Size Impact (30 minutes)
Use parameter: (100 CYCLES ONLY)
Initial number of students Test:

Students	Avg Attention	Avg Performance
10	**0.838913658**	**0.860049505**
25	**0.834340134**	**0.854772277**
60	**0.821190679**	**0.844711221**
100	**0.836408778**	**0.856509901**

Analysis Questions:

1. Does increasing class size affect average attention?
   - Yes, slightly. Attention was highest with 10 students (0.838) and gradually decreased as class size grew, with 60 students having the lowest attention (0.821). However the difference is minimal since all class sizes maintained attention above 0.82.

2. Does mobility create more randomness?
   - Yes. With more students moving around, there is more random variation in attention values. This is visible in the slight variation across different class sizes, such as 100 students (0.836) having slightly higher attention than 60 students (0.821), which shows random movement patterns affecting the results.

3. Is emergent behavior visible?
   - Yes. No single student was programmed to produce the class average, yet a consistent attention and performance pattern emerged across all class sizes. All groups independently reached similar performance values (around 0.85) through the collective behavior of individual agents following simple rules, which is the definition of emergent behavior.

PART 6 — Data Analysis Task (Optional Python)
Using Excel or Power Query Editor

1. Load classroom_data.csv
2. Plot:

o Attention vs Cycle || o Performance vs Cycle

3. Identify break cycles.
4. Compute correlation between attention and performance.

The correlation between attention and performance is -0.056

Question:

Is performance strongly dependent on attention?

- No, performance is not strongly dependent on attention. The correlation is −0.056, which is very close to 0. This means there is almost no relationship between attention and performance. So even if attention changes, performance does not change much because of it.

PART 7 — Critical Thinking Questions

1. Why does performance only increase when attention > 0.6?
   - Because 0.6 represents the minimum level of focus needed for a student to actually learn. Below that level, students are too distracted to absorb the lesson and gain no performance improvement.

2. Is this model deterministic or stochastic?

   - The model is stochastic. Student movement and initial positions are random, meaning each simulation run produces slightly different results even with the same rate.

3. What real-world classroom factors are missing?

   - Several factors are missing such as teacher presence, peer influence, student motivation, subject difficulty, distractions like phones, and individual differences between students like learning pace and prior knowledge.

4. How would peer influence affect the system?
   - If students near highly focused peers gained attention, average attention would increase overall. Students who are losing focus could be pulled back up by engaged classmates, resulting in higher performance and a more stable classroom environment.

PART 8 — Advanced Extension Tasks (Choose One)
Option C: Fatigue Model
Add:
• If attention < 0.3 for 10 cycles → performance decreases.

Option C adds a fatigue model where if a student's attention stays below 0.3 for 10 consecutive cycles, their performance begins to decrease. This represents real-world situations where students who are distracted for too long not only stop learning but also start to forget what they already knew.

Simulation:

10 students

25 students

60 students

100 students
